

A circular queue is a kind of queue where the last spot is connected to the first spot. This helps to avoid wasting memory like we do in a linear queue.

We use two variables, front and rear to keep track of the last things in the queue. When the rear gets to the last spot it will move back to the first spot if there is room. We call this the wrap-around logic, which is used in a queue like this. The circular queue is really good, at handling this kind of thing.
